A PERMANENTLY ON TRANSISTOR IMPLEMENTED USING A DOUBLE
POLYSILICON LAYER CMOS PROCESS WITH BURIED CONTACT

BACKGROUND OF THE INVENTION

10

1. Field of the invention

15

The present invention relates to the prevention and/or inhibition of reverse
engineering of digital integrated circuits, and more particularly to covertly turning a
transistor permanently ON via a double-polysilicon layer CMOS process with buried
interconnects and to an integrated circuit structure comprising the same.

2. Description of the related art

20

The design, development and manufacturing efforts pertaining to semiconductor
integrated circuits involve the understanding of complex structures, processes and
manufacturing techniques involving smaller and smaller electronic circuitry. Efforts to
be able to achieve such understanding and establish successful design, development and
production manufacturing of such integrated circuits involve many man-hours of
highly skilled professionals and considerable expense.

25

On the other hand, to avoid costly man-hours and other significant expenses some
developers resort to reverse engineering practices wherein existing devices are taken
apart, probed and otherwise examined to determine the physical structures of the
resultant integrated circuit under review for subsequent copying. This reverse
engineering, which typically relies primarily on obtaining planar optical image of the
circuit, in essence attempts to by-pass typical product development efforts and expenses
by studying and copying a competitive product.

30

Various approaches have been developed in an attempt to thwart such reverse
engineering efforts, particularly in the field of semiconductor integrated circuits.

For example, US Pat. No. 5,866,933 in the name of the same inventors of the present application teaches how transistors in a CMOS circuit can be connected by hidden lines between the transistors, via modifying the P+ and N+ source/drain masks. These
5 implanted interconnections are further used to make a 3-input AND and OR circuit look substantially the same.

Moreover, US Pat. No. 5,783,846 in the name of the same inventors of the present application teaches a further modification in the source/drain implant masks so that the
10 implanted connecting lines between transistors have a gap inserted, the length of which is approximately the length of the feature size of the CMOS technology being used. If the gap is "filled" with one kind of implant (depending on the implanted connecting line being P or N) the line conducts. But, if the gap is filled with the other kind of implant the line does not conduct. These gaps are called "channel blocks". Thereby the reverse
15 engineer must determine connectivity on the basis of resolving the n or p implant at the minimum feature size of the channel block. Moreover, transistor sizes and metal connection routings are modified; to eliminate keys by which the reverse engineer can find inputs, outputs, gate lines etc. as keys to the circuit functionality.

20 However, integrated circuits protected with the art taught and referenced above look different from standard integrated circuits produced with the same CMOS process. This gives the reverse engineer an indication that something in the circuit at hand is different.

25 SUMMARY OF THE INVENTION

Designing a circuit to appear as one function, but operate as another, is a good way to protect a circuit against reverse process engineering. The present invention applies to the following genre of CMOS fabrication processes.

30 The process according to the present invention employs at least two polysilicon layers. Such is the case in virtually all CMOS processes that manufacture DRAMs and

EEPROMs. Moreover, the process according to the present invention makes use of a buried contact process.

The process according to the present invention provides selected transistors within the integrated circuit that are permanently ON despite the fact that they will look to the reverse engineer as normally functioning transistors.

In this way, the present invention overcomes the problems of the prior art by making use of a buried contact technique to make permanently turned-ON transistors in a double polysilicon CMOS process. In particular, as further disclosed in the present invention, both polysilicon layers can be deposited before source and drain implants.

A buried contact is a known structure in integrated circuit fabrication technology, firstly developed in the late 70's with nMOS circuits. A buried contact provides a direct connection between polysilicon, normally the gate of a MOS transistor, and the source/drain region of a MOS transistor. To create buried contacts, contact openings are masked and etched after gate oxide growth and before deposition and patterning of polysilicon. In this way the polysilicon over the source and/or drain regions can make direct contact to the source and/or drain regions by means of the buried contact openings. See for example S. M. Sze, VLSI Technology, McGraw-Hill, pages 461-478.

The present invention makes use of buried contacts to create permanently ON transistors that look identical to normal transistors. As a result, circuits can be designed to appear as performing one function but in fact perform another. Neither the ON transistors nor the other transistors require that polysilicon be deposited after source and drain implantation, as required by the prior art.

This also means that the present invention, which can be used with the art referenced above, or by itself, does not change the overall appearance of the integrated circuit. That is because the turning of the transistor permanently ON is accomplished in a covert manner.

According to a first aspect of the present invention, a permanently-ON MOS transistor is provided, comprising: a silicon source region of a first conductivity type; a silicon drain region of the first conductivity type; a silicon well region of a second conductivity type, in which said source region and drain region are buried; a silicon contact region of the first conductivity type, buried in the well region, said contact region contacting said source region and said drain region; a first gate insulating layer selectively placed over the silicon source region and the silicon drain region; a second gate insulating layer selectively placed over the first gate insulating layer and over the silicon contact region; and a polysilicon gate region placed over the second gate insulating layer.

According to a second aspect of the present invention, an integrated circuit structure for MOS-type devices is provided, comprising at least one permanently-ON MOS transistor, said transistor including: a first silicon source region of a first conductivity type; a first silicon drain region of the first conductivity type; a first silicon well region of a second conductivity type, in which the first silicon source region and the first silicon drain region are buried; a silicon contact region of the first conductivity type, buried in the well region, the contact region contacting the silicon source region and the silicon drain region; a first gate insulating layer selectively placed over the silicon source region and the silicon drain region; a second gate insulating layer selectively placed over the first gate insulating layer and over the silicon contact region; and a first polysilicon gate region placed over the second gate insulating layer.

According to a third aspect of the present invention, a process is provided for forming a permanently-ON MOS transistor comprising the steps of: providing a silicon well region of a first conductivity type; depositing a first insulating layer over the silicon well region of the first conductivity type; removing a portion of said deposited first insulating layer; forming a buried silicon region of a second conductivity type within the silicon well region of the first conductivity type, under the removed portion of said deposited first insulating layer; depositing a second insulating layer over the first insulating layer and over the buried silicon region of the second conductivity type;

forming a polysilicon gate region over the second insulating layer; and forming a source region of the second conductivity type and a drain region of the second conductivity type within the buried silicon well region, said source region and drain region contacting said buried silicon region of the second conductivity type.

5

BRIEF DESCRIPTION OF THE DRAWINGS

The present invention will be understood and appreciated more fully from the following detailed description taken in conjunction with the drawings, in which:

10

Figure 1 is a cross section of a circuit structure showing buried contacts in which the present invention can be realized;

Figure 2 is a top plan view of two MOS transistors, one of which is turned on according to the present invention;

15

Figure 3 is a cross section taken along line A -A of figure 2;

Figure 4 is a top plan view of four MOS transistors in a CMOS configuration, two of which are turned on according to the present invention;

Figure 5 is a cross section taken along line B-B of figure 4; and

Figure 6 is a cross section taken along line C-C of figure 4.

20

DETAILED DESCRIPTION OF THE INVENTION

Reference will be now made to the drawings that are shown for the purpose of describing the preferred embodiment of the invention and not for limiting same.

25

In the following figures 1 to 3 the N-type buried contacts are shown, i.e. a P-well silicon region having N+ type buried contact implants and N+ type source/drain active regions. Similarly, P-type buried connections will require P+ type source/drain connections and P+ type buried contact implants.

30

In a double polysilicon CMOS process with buried contact, the buried contact is usually opened with masking and doped with the appropriate (i.e. N+ or P+ depending on the type of transistor) implant after the first gate oxide growth. A first layer of polysilicon is deposited to make connection to the source and drain area in the buried contact. The first layer of polysilicon can also be used to form the gate of the transistor with the first gate oxide.

In an EEPROM circuit, the first layer of polysilicon is used as the floating gate for the memory and functions as the bottom plate of a capacitor formed between the first layer and the second layer of polysilicon. The second layer of polysilicon is therefore the upper plate of a capacitor and is used as the gate of the transistor over a gate oxide having a thickness which is the sum of the thicknesses of the first and of the second oxide.

Polysilicon has long been used to form the gates for MOS transistors (see for example S.M. Sze, Op. Cit., page 99) and this requires a CMOS process having one level of deposited polysilicon. CMOS processes employing two polysilicon layers, the two layers typically being separated by an oxide layer, make possible the formation of capacitors and electrically erasable programmable read only memories (EEPROM), see Hodges and Jackson, Analysis and Design of Digital Integrated Circuits, 2nd edition, McGraw-Hill, 1998, page 353.

Figure 1 shows the cross section of the P-well portion of a CMOS integrated circuit in which a buried contact structure is shown, both where contact is made (left side of Figure 1) and where contact is not made (right side of Figure 1). Field insulating regions of the CMOS integrated circuit, for example field oxide regions, are indicated by numeral 1, while first gate insulating regions, for example first gate oxide regions, are indicated by the numeral 2. Numeral 3 indicates a silicon well region of a first conductivity type, in this embodiment a P-well region. The field oxide shown here can be, for example, conventional LOCOS (LOCAl Oxidation of Silicon) oxide. Buried regions of a second conductivity type, in this embodiment N+ regions, are implanted in

the P well 3. The buried region 5 is contacted by a first polysilicon layer 6. A second gate oxide 7, having a preferred thickness of about 100 Å to 200 Å, is disposed in part over the first polysilicon layer 6, in part over the first gate insulator 2 and in part over buried N+ regions like the buried N+ regions 15.

- 5 In general, the first and the second layer gate oxide are not deposited over the LOCOS regions 1. However, embodiments in which this occurs could also be possible.

10 A second polysilicon layer 8 is placed over the N+ region 15, isolated therefrom by means of the second gate oxide 7. Finally, buried source/drain (S/D) regions 9 are present, formed, for example, through ion implantation. It should be noted that the first polysilicon layer 6 makes contact to the N+ region 5 and is connected to the source/drain regions 9 through such region 5. On the contrary, the second polysilicon layer 8, though it also has buried contact opening and implant, is isolated from the N+ region 15 by means of the second gate oxide 7. Moreover, all the S/D regions 9 can be
15 implanted after deposition of the polysilicon layers 6, 8.

Thus, the left part of Figure 1 shows a conventional buried contact (i.e. the N+ region 5 contacts the first polysilicon layer 6), while the right part of Figure 1 shows a buried contact 15 (separated from the second polysilicon layer 8 by a gate oxide 7) which can
20 be used in order to realize a permanently ON transistor as shown in the following figures.

In accordance with the preferred embodiment of the present invention, a permanently ON transistor is implemented in a double polysilicon layer CMOS integrated circuit like
25 the one described in Figure 1. As it will be appreciated by the person skilled in the art, the permanently ON transistor can be implemented in NMOS and PMOS structures as well.

Figure 2 shows a top plan view of two transistors, wherein transistor 21 is a
30 permanently-ON transistor realized according to the present invention and transistor 23 is a normal transistor. Transistor 21 has a polysilicon gate 8' and source/drain

regions 9', together with a buried contact opening 22. Transistor 23 has a polysilicon gate 8'' and source/drain regions 9'', with no buried contact openings. Of course, the buried contact opening 22 is shown for clarity purposes only and it is invisible when viewing the circuit from the top. Therefore, transistor 21 is identical to transistor 23 when viewed from the top.

Figure 3 is a cross section taken along line 3 - 3 of figure 2. With reference to the source/drain regions 9' of transistor 21, it should be noted that they are short-circuited by the implanted N+ region 15. The result of this is that transistor 21 is turned ON permanently. Because of the buried contact being located at the channel region, the etching process of the buried contact opening only created a step of the thickness of the second gate oxide 7, around 100 Å to 200 Å thick. This step is very difficult to identify during a reverse engineering process and makes the permanently ON transistor 21 very difficult to detect and to distinguish from a non-permanently ON transistor like transistor 23.

Figure 4 is a top plan view of four MOS transistors in a CMOS configuration, two of which are turned on according to the present invention. Transistors 41 and 42 are permanently-ON transistors realized according to the present invention and transistors 43 and 44 are normal transistors. Transistor 41 has a buried contact opening 45 and transistor 42 has a buried contact opening 46. Again, the buried contact openings are shown for clarity purposes only and are invisible when viewing the circuit from the top.

Figures 5 and 6 are cross sections taken along lines 5-5 and 6-6 of figure 4 respectively. The description of those figures is similar to the description of figure 3.

The invention has been described with reference to a particular embodiment. Modifications and alterations will occur to others upon reading and understanding this specification. It is intended that all such modifications and alterations are included insofar as they come within the scope of the appended claims or equivalents thereof.
